**ABSTRACT:** Disclosed here is a catalytic strategy for asymmetric access to chiral tetrasubstituted silicon-stereogenic silanes. Our reaction starts with a (covalently) symmetric silane bearing two aldehyde moieties as the substrate. Single-crystal structural analysis shows that the substrate exists as a racemate of two conformational enantiomers because of the presence of a Si/O weak interaction. Mechanistic studies assisted by DFT calculation indicate that the two conformational enantiomers can readily isomerize to each other, and one of the conformational enantiomers of the substrate is favorably activated by a N-heterocyclic carbene catalyst via an overall desymmetrization process to eventually afford optically enriched tetrasubstituted silicon-stereogenic silanes as the products. Our chiral silanes' products can be readily transformed to a diverse set of silicon stereogenic functional molecules.

**KEYWORDS:** chiral tetrasubstituted silicon-stereogenic silane, N-heterocyclic carbene, organocatalysis, conformational enantiomers resolution, density functional theory calculations

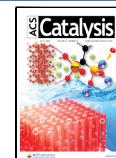

Silicon is the second most abundant element in the crust. Although the natural appearance of silicon in living systems is uncommon, the incorporation of this element into organic molecules has led to impressive applications as medicines and agrochemicals<sup>1</sup> (Figure 1a). Examples of such silicon-atom-containing medicines and pesticides include Karenitecin,<sup>1e</sup> Flusilazole,<sup>1a</sup> and Silaflufen.<sup>1b</sup> Indeed, various molecules containing silicon have been commercialized as pesticides, and more candidates are being developed at various stages.<sup>2</sup> Outside of biological applications, silicon-containing organic molecules have been found applications in many areas such as materials<sup>3</sup> and catalysis.<sup>4</sup> It has now been well recognized that replacing carbon with silicon atoms in organic molecules can lead to improved and/or alternative functions.<sup>2a,b,5</sup> However, methods for the synthesis of silicon-containing molecules remain underdeveloped. The synthetic challenge further increases when silicon-stereogenic center are to be constructed. The Si—C bond is longer than the corresponding C—C bond, making it difficult to form well-organized transition states.<sup>2b,6</sup> In

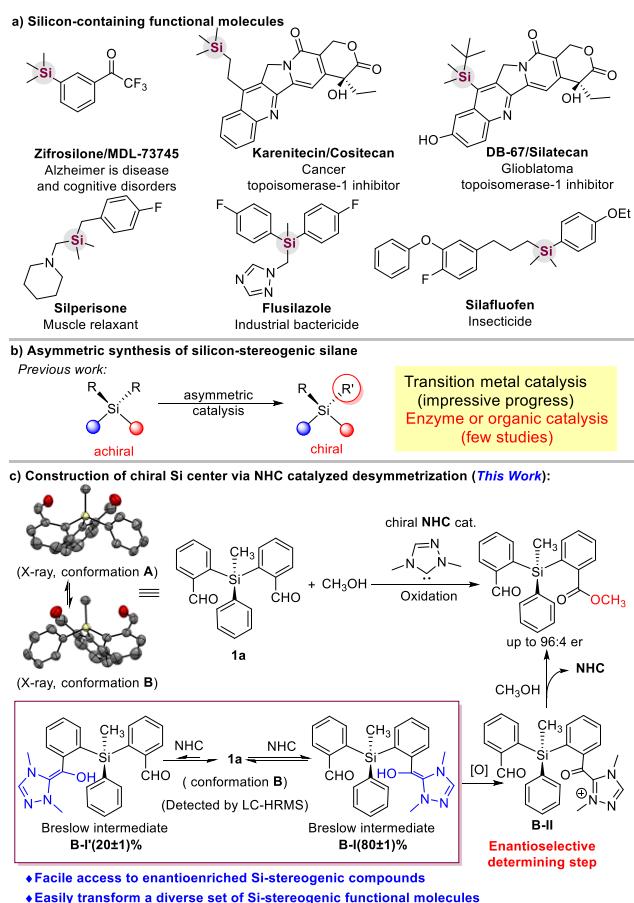

addition, silicon can form more than four covalent bonds and thus lead to racemization of the stereogenic center.<sup>7</sup> To date, the impressive yet still limited success for asymmetric synthesis of silicon-stereogenic center-containing molecules are exclusively achieved via transition-metal-catalyzed reactions<sup>8</sup> (Figure 1b). These methods use chiral ligand/metal complexes-catalyzed processes to form new carbon–silicon bond or selectively functionalize one of the two pro-chiral groups attached to the silicon atom.<sup>8</sup> Enzymes and organic catalysts have found enormous applications in building carbon chiral centers. Unfortunately, in the area of silicon-stereogenic center synthesis, few reactions are developed using enzymes<sup>9</sup> or organic catalysts.

**Figure 1.** Silicon-containing bioactive molecules and asymmetric access to chiral silicon-stereogenic silanes.

We believe it is worthwhile to explore the potentials of organic catalysis to construct silicon atom chiral centers.

Here we disclose an N-heterocyclic carbene (NHC)-catalyzed<sup>10</sup> desymmetrization reaction for access to tetrasubstituted silicon-stereogenic silanes (Figure 1c). The overall catalytic process converts one of the two aldehyde moieties of the Si-containing dialdehyde substrate to a carboxylic ester group, leading to tetrasubstituted silicon-stereogenic silanes with high optical purities. Our experimental observations and DFT calculations on key reaction steps suggest that the addition steps and formation of Breslow intermediate between the NHC catalyst and the dialdehyde substrate did not provide sufficient differentiations. Instead, stereodetermining and desymmetrization were realized during the formation of acylazoumion intermediate. Our transition-metal-free catalytic reaction conditions are mild with good functional group tolerance. The optically enriched silicon-stereogenic products from our method can be readily transformed to a diverse set of molecules with the silicon stereogenic center remaining intact.

We initiated our studies on the construction of a silicon-stereogenic center using 2,2'-(methyl(phenyl)silanediyl)-dibenzaldehyde **1a** and methanol **2a** as model substrates to search for suitable conditions, with key results summarized in Table 1. NHC precatalyst **A**<sup>11</sup> bearing an N-Mes group could promote the reaction smoothly in an enantioselective fashion, and the silicon-stereogenic silane product **3a** was obtained in moderate enantioselectivity and excellent yield (Table 1, entry 1). NHC precatalysts **B**<sup>12</sup> or **C**<sup>13</sup> bearing N-Ph or N-C<sub>6</sub>F<sub>5</sub> groups were not efficient for the reactions (Table 1, entries 2 to

<sup>a</sup>Unless otherwise specified, the reactions were carried under N<sub>2</sub> atmosphere using **1a** (0.10 mmol), **DQ** (0.10 mmol), **2a** (0.11 mmol), pre-NHC (0.02 mmol), base (0.02 mmol), solvent (2.0 mL), 30 °C, 12 h. <sup>b</sup>Isolated yield of **3a**. <sup>c</sup>The er values of **3a** were determined via HPLC on the chiral stationary phase. <sup>d</sup>0.005 mmol pre-NHC **D** was used.

3). To our delight, when NHC precatalyst **D**<sup>14</sup> bearing a nitro group was employed, the product **3a** was further improved in an 82% yield and 91:9 er (Table 1, entry 4). Therefore, we used the NHC precatalyst **D** for the examination of different bases in this protocol. Switching K<sub>2</sub>CO<sub>3</sub> to other inorganic bases or organic bases led to a drop in the product yields (Table 1, entries 5 to 9). Solvents also had a clear impact on the reaction outcomes, and CH<sub>3</sub>CN performed the best to give **3a** with 84% yield and 96:4 er (Table 1, entries 10 to 12). Further decreasing the loading of the NHC precatalyst **D** would result in a drop in the product yield (Table 1, entry 13).

With an optimal reaction condition in hand, we explored the reaction scope of 2,2'-(methyl(phenyl)silanediyl) dibenzaldehyde **1**, different substitution patterns of **1** were examined (Scheme 1). Both electron-donating (**3b**, **3c**, **3f**) and electron-withdrawing (**3d**, **3e**, **3g**) substituents can be introduced into the 4- and 5- positions (relative to the silicon moiety) on the phenyl ring **A** of **1**, with the corresponding desired products afforded in good to excellent yields and high enantioselectivities. When the reaction time was increased from 12 to 24 h, the desired product **3h** and **3i** can be afforded in moderate to excellent yields and high optical purities. When the electron-withdrawing group,

**Scheme 1.** Scope of 2,2'-(Methyl(phenyl)silanediyl)dibenzaldehyde **1**<sup>a</sup>

<sup>a</sup>Reaction conditions as stated in Table 1, entry 12. Yields are isolated yields after purification by column chromatography. Er values were determined via HPLC on chiral stationary phase. <sup>b</sup>The reaction was carried out at 3.0 mmol scale based on **1a**, reaction time was 48 h. <sup>c</sup>Reaction time was 24 h. <sup>d</sup>The reactions were carried out using 0.005 mmol pre-NHC **D**. <sup>e</sup>The reaction was carried out by using THF as solvent, and reaction time was 24 h. <sup>f</sup>The reaction time was 24 h, the yield is determined by <sup>1</sup>H NMR using CH<sub>2</sub>Br<sub>2</sub> as internal standard.

such as Cl/CF<sub>3</sub> at 4- or 5-position were installed on the phenyl ring **A** of **1**, the moderate yields and er values were obtained for the desired products, and the diester byproducts were found in the reactions. Subsequently, it was found that decreasing the NHC catalyst loading (5 mol %) led to slightly improve the yields and enantioselectivities of these products (**3j–3m**).

Additionally, the low NHC catalyst loading (5 mol %) was examined for all the substrates, and most substrates were not totally converted to corresponding products after 12 h (see SI).

The generality of different types on the phenyl ring **B** of **1** were also examined (Scheme 1). Placing different substituents on the 4-positions of the phenyl ring **B** resulted in good to

excellent enantioselectivities (**3n** to **3x**). When the aromatic ring B was replaced by a piperonyl ring and a naphthalene ring, the desired products can be afforded in excellent yields and high optical purities (**3y** and **3z**). Only a trace amount of the target products was observed under the standard reaction condition when the heterocyclic ring was introduced to aromatic ring B. By switching  $\text{CH}_3\text{CN}$  to THF, the **3aa** and **3ab** can be obtained in moderate yields and excellent enantioselectivities. The methyl group of **1** was replaced with other aliphatic moieties, and the corresponding products (**3ac** to **3af**) were afforded in good yields and excellent enantioselectivities. Additionally, different types of nucleophiles were also examined, and the target products were also obtained (**2b** to **2e**) in moderate yields and high optical purities.

Furthermore, the enantioenriched silicon stereogenic monocarboxylate ester product **3a** was easily transformed into various derivatives through simple protocols (Figure 2). For instance,

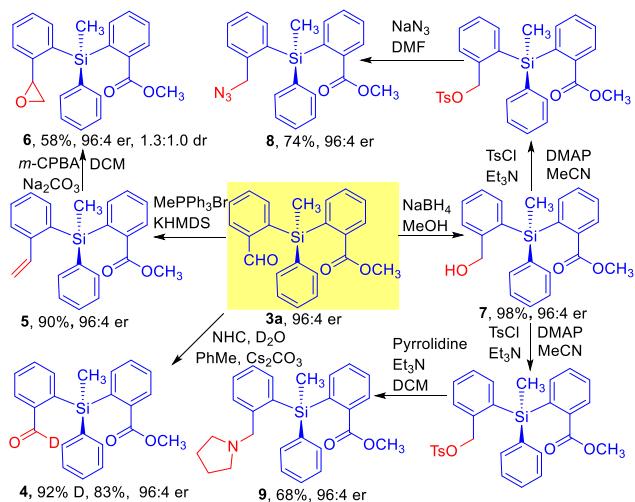

Figure 2. Synthetic transformation of **3a**.

the hydrogen atom of aldehyde could be catalyzed by achiral NHC with the presence of  $\text{D}_2\text{O}$  to afford 92% deuterated **4** in 83% yield and 96:4 er. Compound **3a** could react with the Wittig reagent to give alkene **5** with 90% yield and 96:4 er. This carbon–carbon double bond of alkene **5** could also be epoxidized with *m*-CPBA to form epoxide **6** without reduction of the optical purity. The aldehyde moiety in **3a** was reduced by  $\text{NaBH}_4$  to form the corresponding alcohol **7** with 98% yield and 96:4 er. The hydroxyl group in alcohol **7** was reacted with toluene sulfonyl chloride and subsequently reacted with sodium azide to form product **8** with 74% yield and 96:4 er. The product **9** could also be easily obtained in good yield and excellent enantioselectivity from alcohol **7**.

To understand the mechanism of our desymmetrization approach, single-crystal structure analysis and density functional theory (DFT) calculations were performed. In the single-crystal X-ray structure of **1a** (CCDC:2151740), two conformational enantiomers were found in the unit cell (Figure 3). It suggests the presence of a weak interaction between silicon and oxygen atom (bond length less than 2.90 Å). This weak interaction breaks the symmetry of **1a** and makes the entire molecule with helical chirality; therefore, this symmetric silicon-bridged dibenzaldehyde is present as a racemic mixture of two conformational enantiomers. The interconversion of the two

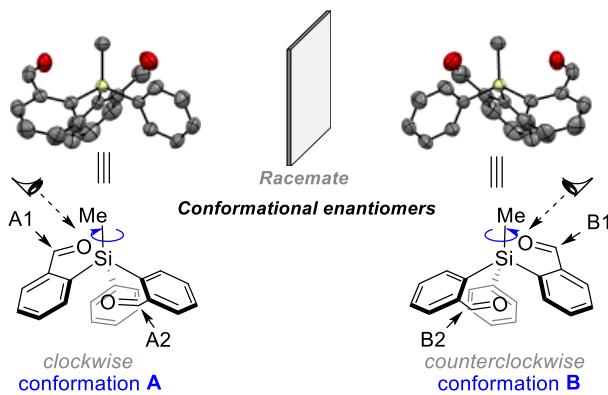

Figure 3. Unit cell analysis of **1a**.

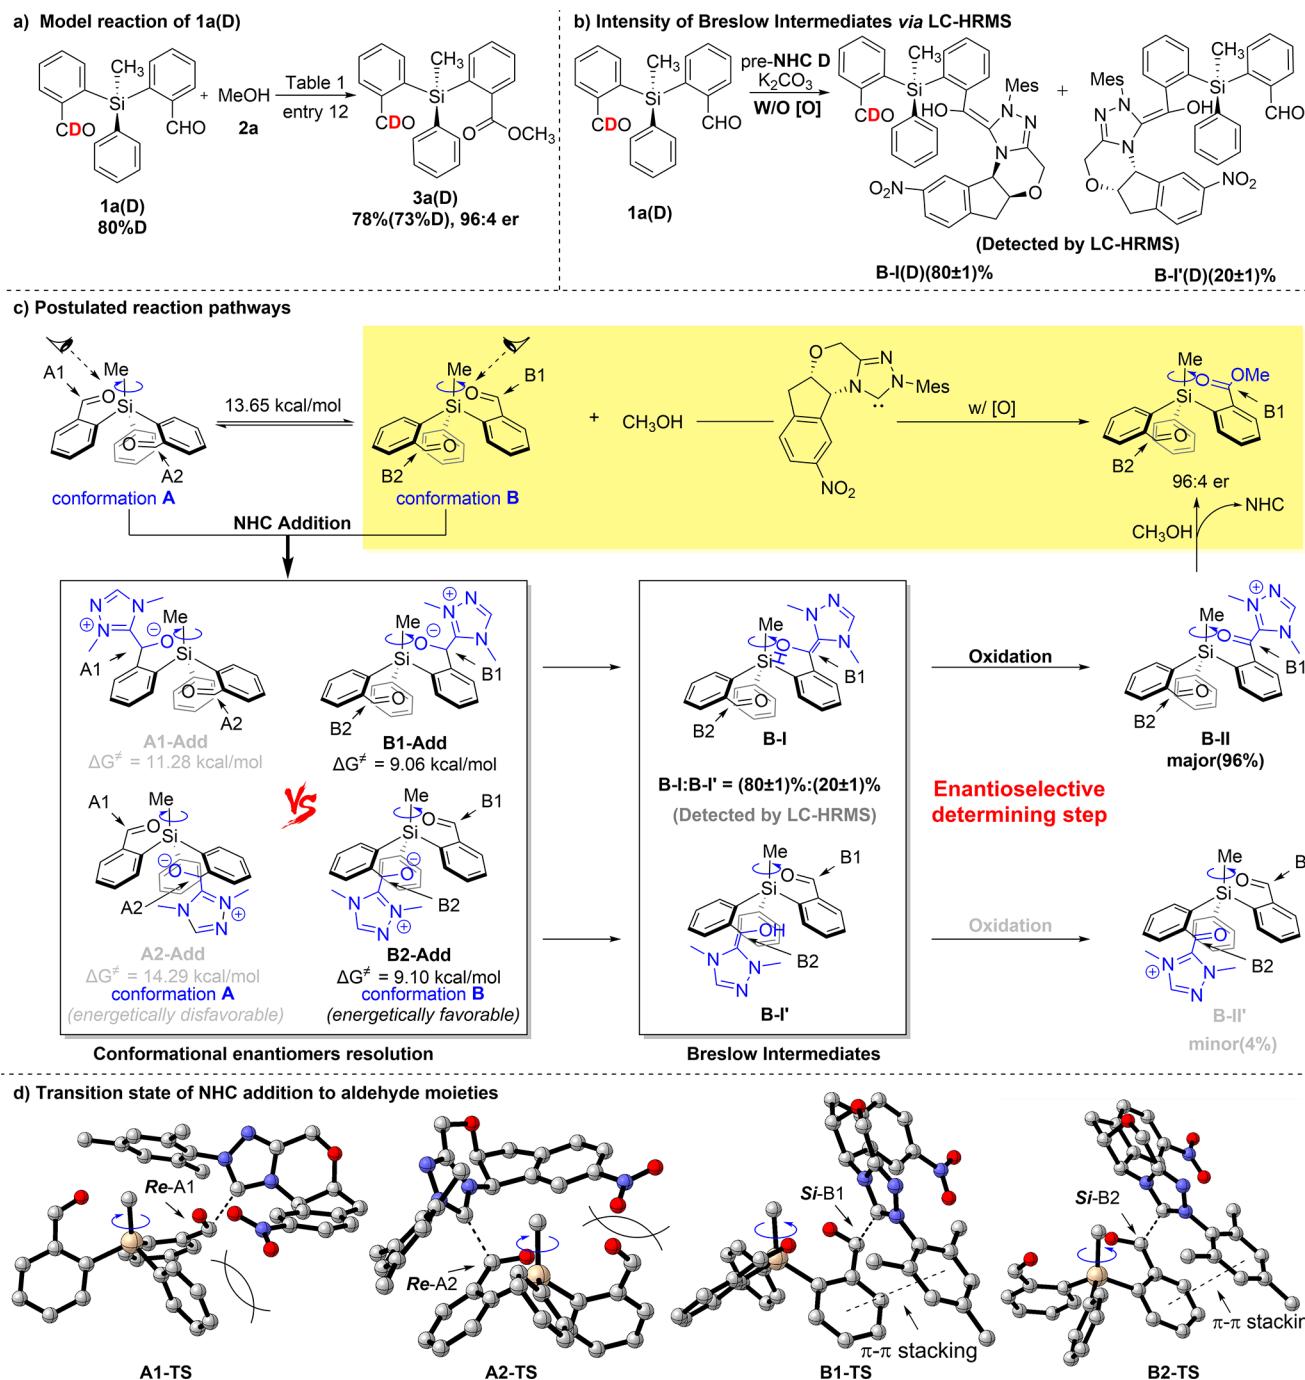

conformational enantiomers was a facile process, and the conversional energy barrier is 13.56 kcal/mol (Figure 4a).

To further investigate the mechanism of the reaction, some additional experiments were performed. The S-**3a** (96:4 er) was employed to synthesize the single deuterium-labeled (abbreviated as D-labeled) aldehyde moiety substrate **1a(D)**, and the absolute configuration of **1a(D)** still remained intact. Then **1a(D)** was reacted with methanol (Table 1, entry 12). Subsequently, the D-labeled product **3a(D)** was obtained in 78% yield and 96:4 er, and the reaction result was similar to nondeuterium-labeled model reaction (Figure 4a). It suggests that the D-labeled **1a(D)** can be used as a model substrate to study the chemo-selectivity in reactions.

The **1a(D)** was used to react with carbene catalyst without oxidant to form two diastereoisomers Breslow intermediates **B-I(D)** and **B-I'(D)** with different molecular weight (Figure 4b). The corresponding intensity of the D-labeled and nonisotope labeled Breslow intermediates were detected and differentiated by LC-HRMS. It was found that the intensity ratio of **B-I(D)** and **B-I'(D)** was  $(80 \pm 1\%):(20 \pm 1)\%$ , which means that overall the carbene addition and formation of Breslow intermediate was an enantioselective step.

Furthermore, the additions of NHC catalyst to a single aldehyde moiety in the two conformational isomers (two set of enantiomers; four possibilities for the additions) were evaluated, and the full NHC structure was employed for the DFT calculations (Figure 4c). We found that the aldehyde moieties of conformation **B** can be more easily reacted with NHC catalyst ( $\Delta G^\ddagger = 9.10, 9.06$  kcal/mol), and the addition energy barriers were lower than conformation **A** ( $\Delta G^\ddagger = 14.29, 11.28$  kcal/mol). In conformation **B**, the difference of Gibbs free energy barriers ( $\Delta \Delta G^\ddagger = 0.04$  kcal/mol) between the NHC catalyst addition to the **B1/B2** aldehyde moiety was very small. This  $\Delta \Delta G^\ddagger$  of 0.04 kcal/mol disfavors the observed enantioselectivity by 1.00:1.06 and translates to an er value of about 52.00:48.00. The transition states of **B1-TS** and **B2-TS** have a lower activation barrier because of the favorable  $\pi-\pi$  stacking interactions between the aryl ring of the NHC and **1a**, which stabilize the transition states. These steric-blocking interactions are present in **A1-TS** and **A2-TS**, which lead a higher energy barrier in the addition process (Figure 4d).

In summary, we have developed a NHC-catalyzed desymmetrization approach for access to enantioenriched silicon stereogenic silanes. Our reaction starts with silicon-bridged dibenzaldehyde as the substrate. The two aldehyde moieties of the substrate are symmetric in terms of covalent linkages. However, X-ray structure analysis indicates that noncovalent

**Figure 4.** Postulated reaction pathways supported by control experiment and DFT calculation of key steps.

interactions break the symmetry and the substrate is present as a racemate of two conformational enantiomers. Mechanistic studies assisted by DFT calculation suggest the reaction proceeds via conformational isomerization and NHC-mediated desymmetrization to eventually afford tetrasubstituted silicon-stereogenic silanes with excellent yields and enantiomeric excesses. The chiral silanes from our reactions can be readily transformed to other molecules with the silicon-stereogenic remaining. Further studies on the bioactivities of these silane compounds for agricultural applications are in progress in our laboratories. Our method and its mechanistic implications could also stimulate further investigations on the conformational structures of silanes and their asymmetric synthesis.
